Wiener-Hopf factorization as a general method for valuation of barrier options, American options and real options

Svetlana Boyarchenko and Sergei Levendorskiǐ

University of Texas at Austin, University of Leicester

November 20, 2008
Aim of the talk: to explain

**A general approach to pricing** barrier options, real options, American options and other optimal stopping problems in Lévy models, including regime-switching models

Regime-switching models can be used to approximate models with

- stochastic interest rates
- stochastic volatility
- mean reversion
Outline

1. Lévy processes: general definitions and examples
2. No-arbitrage pricing
3. European options
4. Barrier options and generalized Black-Scholes equation
5. American options and free boundary problems
6. Carr’s randomization
7. Perpetual American options and real options
8. EPV-operators and Wiener-Hopf factorization
9. Model situations
10. Regime-switching models
11. Finite time horizon
12. 3-factor model
Lévy processes: general definitions

$L$, infinitesimal generator, and $\psi$, characteristic exponent of $X = (X_t)$:

$$E \left[ e^{i\xi X_t} \right] = e^{-t\psi(\xi)}, \quad Le^{i\xi x} = -\psi(\xi) e^{i\xi x}$$

Hence, $L = -\psi(D)$ is the PDO with symbol $-\psi(\xi)$. In 1D,

$$Lu(x) = (2\pi)^{-1} \int_{\mathbb{R}} e^{ix\xi} (-\psi(\xi)) \hat{u}(\xi) d\xi.$$

Explicit formulas (Lévy-Khintchine) are (also in 1D)

$$\psi(\xi) = \frac{\sigma^2}{2} \xi^2 - i\mu \xi + \int_{\mathbb{R} \setminus 0} (1 - e^{iy\xi} + iy\xi \mathbb{1}_{|y|<1}(y)) F(dy),$$

$$Lu(x) = \frac{\sigma^2}{2} u''(x) + \mu u'(x) + \int_{\mathbb{R} \setminus 0} (u(x+y) - \mathbb{1}_{|y|<1}(y)yu'(x) - u(x)) F(dy),$$

where $F(dy)$, the Lévy density, satisfies

$$\int_{\mathbb{R} \setminus 0} \min\{|y|^2, 1\} F(dy) < \infty.$$
Some examples

1. **Brownian motion** (no jumps)

2. **Double-exponential model** (Kou (2002)): sizes of jumps are exponentially distributed on each half-axis

\[ \psi(\xi) = \frac{\sigma^2}{2} \xi^2 - i \mu \xi + \frac{ic_+ \xi}{\lambda_+ + i \xi} + \frac{ic_- \xi}{\lambda_- + i \xi}, \]

where \( \sigma > 0, \mu \in \mathbb{R}, c_+ > 0, \) and \( \lambda_- < 0 < \lambda_+ \).

3. **Extended Koponen’s model** Boyarchenko and Levendorskiǐ (1999); a.k.a. CGMY-model (Carr, Madan, Geman, Yor (2002)) and KoBoL model. The Lévy density behaves as \( c |y|^{-\nu - 1} \) near \( 0 \) and exponentially decays at infinity. For \( \nu \in (0, 2), \nu \neq 1, \)

\[ \psi(\xi) = -i \mu \xi + c \Gamma(-\nu) [\lambda_+^\nu - (\lambda_+ + i \xi)^\nu + (-\lambda_-)^\nu - (-\lambda_- - i \xi)^\nu], \]

where \( c > 0, \mu \in \mathbb{R}, \) and \( \lambda_- < 0 < \lambda_+ \).
Regime-switching and multi-factor models

Markov-modulated Lévy model: e.g.,
different stock price dynamics in booms and recessions

\[ L_S = [\lambda_{jk}]_{j,k=1}^m \] : the generator of a Markov chain

For each \( j \), \( L_j \) : the generator of a Lévy process

Markov-modulated Lévy process: the generator \( L_S \otimes I + \text{diag}(L_j) \)

Models with stochastic volatility and/or stochastic interest rate

Additional stochastic factors with mean-reversion. The infinitesimal
generator is of the form \( L_Y + c(y)L_X + \mu(y)\partial_x - r(y) \),
where \( L_Y \) acts w.r.t. \( y \) and \( L_X \) w.r.t. \( x \).

State space: the cartesian product of \( \mathbb{R}_x \) and a subset of \( \mathbb{R}_y^n \)

**Appropriate discretization** of the state space for \( Y \) and discretization of \( L_Y \) leads to a **regime-switching model**.
No-arbitrage pricing of options on the underlying asset (e.g., stock, with the price process $S_t$)

Assuming that the riskless rate $r > 0$ is fixed, the discounted price process is a martingale under $\mathbb{Q}$, an equivalent martingale measure (EMM) (chosen by the market):

$$e^{-rt} S_t = \mathbb{E}^Q_t [e^{-rT} S_T],$$

for $t < T$, where $\mathbb{E}^Q_t$ is the expectation operator under $\mathbb{Q}$ conditioned on the information available at time $t$, or

$$S_t = \mathbb{E}^Q_t [e^{-r(T-t)} S_T]$$

Any derivative security, e.g., an option on the stock $S_t$, with the price process $V_t$, must be also a (local) martingale under $\mathbb{Q}$: for any stopping time $T \geq t$, which does not exceed the (random) life span of the security,

$$V_t = \mathbb{E}^Q_t [e^{-r(T-t)} V_T]$$
European option with expiry date $T$ and payoff $G(S_T)$

Life-time span is deterministic.

**Call:** $G(S_T) = (S_T - K)_+$. **Put:** $G(S_T) = (K - S_T)_+$

No-arbitrage price:

$$V_t = \mathbb{E}_t^Q [e^{-r(T-t)} G(S_T)]$$

**Numerical calculation:**

i. if pdf of $S_T|S_t$ is available: numerical integration (easy)

ii. in the general case, Monte-Carlo methods are fairly straightforward

iii. if characteristic function of $S_T|S_t$ is available: inverse Fast Fourier Transform (iFFT). The best choice if calculations need to be done fast and at many points.

**There are important computational issues for iFFT**

Levendorskiĭ and Zherder (2001), Lord (2004); especially in higher dimensions N. Boyarchenko and Levendorskiĭ (2007)
Numerous versions, e.g., **down-and-out call option** with strike $K$, expiry date $T$, barrier $H$ and rebate $G_b$. Typically, $H < K$.

Let $\tau$ be the random time when the barrier is reached or crossed from above. If $\tau \leq T$, the option expires and option owner receives the rebate $G_b$. Otherwise, at time $T$, the option owner receives the payoff $G(S_T) = (S_T - K)_+$. 

**No-arbitrage price at time 0:**

$$V_0 = \mathbb{E}^Q[e^{-r\tau}1_{\tau \leq T}G_b] + \mathbb{E}^Q[e^{-rT}1_{\tau > T}(S_T - K)_+]$$
Analytical expressions for the price of a barrier option

i in diffusion models: in many cases, in particular, in the Brownian Motion (BM) model and exponential BM model, explicit analytical formulas are available

ii for certain classes of diffusions with embedded compound Poisson jumps of a relatively simple structure, explicit formulas are derived by several authors starting with Lipton (2001) and Kou (2002), different probabilistic methods being used

iii for wide classes of exponential Lévy models, general analytic formulas were derived by Boyarchenko and Levendorskiǐ (2000) using the Wiener-Hopf technique. An important ingredient was the derivation of the generalization of the Black-Scholes equation
The stock price $S_t = \exp X_t$, where $X_t$ is a Lévy process under $Q$.

The boundary problem for the down-and-out call option:

\[
(r - \partial_t - L)V(t, x) = 0, \quad x > h := \log H, \quad t < T;
\]
\[
V(T, x) = (e^x - K)_+, \quad x \geq h := \log H;
\]
\[
V(t, x) = G_b, \quad x \leq h, \quad t \leq T,
\]

plus the natural condition on the rate of growth as $x \to +\infty$

**GBS equation:** in the sense of the theory of generalized functions

$X$ satisfies **(ACT)-property:** transition densities exist

$\psi$ admits the analytic continuation into the strip $\text{Im } \xi \in [-1, 0]$

Generalizations for Lévy processes in $\mathbb{R}^n$ are also proved
Numerical calculations in the non-gaussian case:

a. General formulas (Boyarchenko and Levendorskiĭ (2000)): not computationally efficient;
b. but help to derive the asymptotics of the price near the barrier: needed to understand why naive approximations cannot work
c. Explicit formulas obtained by probabilistic methods are applicable to jump-diffusion processes which are not observed in the real markets
d. If these processes are used as approximations to more realistic ones (e.g., Cont-Volchkova method; Pistorius with different co-authors), sizable errors result near the barrier
e. Monte-Carlo methods also give sizable errors near the barrier
American options and free boundary problems

The payoff function is the same as in the European case but the exercise time $\tau \leq T$ can be chosen by the option owner.

**Optimal stopping problem:** find an optimal stopping time $\tau \leq T$ for

$$V(0, x) = \max_{\tau} \mathbb{E}^Q\left[e^{-r\tau} G(S_{\tau})\right].$$

The corresponding **free boundary problem**, for the put option, in the exponential Lévy model, is: find the early exercise boundary $x = h(t)$ which maximizes the bounded solution of the problem

$$(r - \partial_t - L)V(t, x) = 0, \quad t < T;$$

$$V(T, x) = (K - e^x)_+;$$

$$V(t, x) = K - e^x, \quad x \leq h(t), t < T.$$

**No analytical solution even in the Gaussian case**
Smooth pasting condition is not mentioned: does not hold in some cases (Boyarchenko and Levendorskiĭ (2002))

For a typical pure jump process used in finance, The price of a barrier option is not smooth up to the boundary; in the diffusion case with exponentially distributed compound Poisson jumps, the price is of class $C^2$ up to the boundary.

For American options, there may be a gap between the early exercise boundary and strike, at expiry, in the classical situations when for diffusion models, there is no gap Boyarchenko and Levendorskiĭ (2002); Levendorskiĭ (2004)

General formula for the gap, for wide classes of Markov processes with jumps Levendorskiĭ (2008)
Most efficient method for calculation of prices of barrier options and American options with finite time horizon $T$: discretize time $(0 = t_0 < t_1 < \cdots < t_N (= T))$ but not the space variable.

The equivalent probabilistic version: **Carr’s randomization**

For **American options**: put, BM - Carr (1998); Lévy processes and general payoff functions - Boyarchenko and Levendorskiĭ (2002); proof of convergence for American options - Bouchard, El Karoui, Touzi (2006)

For the barrier option with payoff $G(X_T)_{+}$, barrier $h$ and no rebate, the result is a sequence of stationary boundary problems, equivalently, a sequence of perpetual barrier options with the same barrier.
Calculate the sequence of approximations to the option value:
\[ v_s(x) = V(t_s, x), \] and to the early exercise boundary: \( h_s = h(t_s), \)
\( s = 0, 1, \ldots, N - 1. \)

1. Set \( v_N(x) = G(x)_+ \)
2. For \( s = N - 1, N - 2, \ldots, 0, \) set \( \Delta_s = t_{s+1} - t_s, q^s = r + \Delta_s^{-1}, \) and find an optimal stopping time \( \tau_s \) which maximizes

\[ v_s(x) = \mathbb{E}^x \left[ \int_0^{\tau_s} e^{-q^s t} \Delta_s^{-1} v_{s+1}(X_t) dt \right] + \mathbb{E}^x \left[ e^{-q^s \tau_s} G(X_{\tau_s}) \right] \]

**How to solve this sequence**, especially for \( G \) of a general form, and a general Lévy process?
Main idea (Boyarchenko and Levendorskiĭ (2002, 2005))

i. Assume that $G(x)$ is the $q^s$-resolvent of a non-increasing function $g_s$, which changes sign:

$$G(x) = \mathbb{E}^x \left[ \int_0^\infty e^{-q^st} g_s(X_t) dt \right]$$

ii. Introduce $\tilde{\nu}_s = \nu_s - G$; maximization of $\nu_s \Leftrightarrow$ maximization of $\tilde{\nu}_s$

iii. Using Dynkin’s formula,

$$\tilde{\nu}_s(x) = \mathbb{E}^x \left[ \int_0^{\tau_s} e^{-q^st} \left( \Delta_s^{-1} \tilde{\nu}_{s+1}(X_t) - g_s(X_t) \right) dt \right]$$

iv. Note that for $s = N - 1$, $\tilde{\nu}_{s+1} = (-G)_+$ is non-decreasing, hence, $g^s := \Delta_s^{-1} \tilde{\nu}_{s+1} - g_s$ is a non-decreasing function which changes sign

v. Hence, for $s = N - 1$, the standard **optimal exit problem**; solution is a non-negative non-decreasing function

vi. By induction, the same argument is valid at each time step
Perpetual American options and real options

Basic problem I (perpetual barrier option) Calculate

\[ V(x; \tau) = \mathbb{E}^x \left[ \int_0^\tau e^{-qt} g(X_t) dt \right], \]

where \( \tau \) is a stopping time. Typically,

- \( \tau = \tau_h^− \): the hitting time of \((-\infty, h]\), or
- \( \tau = \tau_h^+ \): the hitting time of \([h, +\infty)\)

Basic problem II (optimal exit problem)
Find an optimal stopping time \( \tau \) which maximizes \( V(x; \tau) \).

Main technical tools
- expected present value operators (EPV-operators) under a Lévy process and its supremum and infimum processes
- operator form of the Wiener-Hopf factorization
Supremum and infimum processes

- $\overline{X}_t = \sup_{0 \leq s \leq t} X_s$ - the supremum process
- $\underline{X}_t = \inf_{0 \leq s \leq t} X_s$ - the infimum process

Normalized EPV operators under $X$, $\overline{X}$, and $\underline{X}$:

- $(\mathcal{E}^+ g)(x) := q \mathbb{E}^x \left[ \int_0^{+\infty} e^{-qt} g(X_t) dt \right]$
- $(\mathcal{E}^0 g)(x) := q \mathbb{E}^x \left[ \int_0^{+\infty} e^{-qt} g(\overline{X}_t) dt \right]$
- $(\mathcal{E}^- g)(x) := q \mathbb{E}^x \left[ \int_0^{+\infty} e^{-qt} g(\underline{X}_t) dt \right]$. 
Example 1: Brownian Motion. EPV-operators are of the form

\[ \mathcal{E}^+ u(x) = \beta^+ \int_0^{+\infty} e^{-\beta^+ y} u(x + y) dy, \]

\[ \mathcal{E}^- u(x) = (-\beta^-) \int_{-\infty}^0 e^{-\beta^- y} u(x + y) dy, \]

where \( \beta^- < 0 < \beta^+ \) are the roots of \( q + \psi(-i\beta) = 0 \).

Example 2: Kou’s model. EPV-operators are of the form

\[ \mathcal{E}^+ u(x) = \sum_{j=1,2} a_j^+ \beta_j^+ \int_0^{+\infty} e^{-\beta_j^+ y} u(x + y) dy, \]

\[ \mathcal{E}^- u(x) = \sum_{j=1,2} a_j^- (-\beta_j^-) \int_{-\infty}^0 e^{-\beta_j^- y} u(x + y) dy, \]

where \( \beta_2^- < \lambda_+ < \beta_1^- < 0 < \beta_1^+ < \lambda_- < \beta_2^+ \) are the roots of the “characteristic equation” \( q + \psi(-i\beta) = 0 \), and \( a_j^\pm > 0 \) are constants.
Wiener-Hopf factorization formula

Three versions:

1. Let $T \sim \text{Exp}(q)$ be the exponential random variable of mean $q^{-1}$, independent of process $X$. For $\xi \in \mathbb{R}$,

$$
\mathbb{E}[e^{i\xi X_T}] = \mathbb{E}[e^{i\xi X_T}] \mathbb{E}[e^{i\xi X_T}];
$$

2. For $\xi \in \mathbb{R}$,

$$
\frac{q}{q + \psi(\xi)} = \phi_+^q(\xi) \phi_-^q(\xi),
$$

where $\phi_\pm^q(\xi)$ admits the analytic continuation into the corresponding half-plane and does not vanish there.

3. $\mathcal{E}_q = \mathcal{E}_q^- \mathcal{E}_q^+ = \mathcal{E}_q^+ \mathcal{E}_q^-.$

3 is valid in appropriate function spaces, and can be either proved as 1 or deduced from 2 because $\mathcal{E}_q = q(q + \psi(D))^{-1}$, $\mathcal{E}_q^\pm = \phi_\pm^q(D)$. 
Theorem 1

Let $g$ be a measurable locally bounded function satisfying certain conditions on growth at $\infty$. Then for any $h$,

$$V(x; h) = q^{-1} \mathcal{E}_q^+ 1_{(h, +\infty)} \mathcal{E}_q^+ g(x).$$  \hspace{1cm} (1)

The proof is based on the following result

Lemma 2

Let $X$ and $T$ be as above. Then

(a) the random variables $\overline{X}_T$ and $X_T - \overline{X}_T$ are independent (deep!); and
(b) the random variables $\underline{X}_T$ and $X_T - \overline{X}_T$ are identical in law.
Proof of Theorem 1

Let $T \sim \text{Exp } q$ be independent of $X$. Then $\mathcal{E} g(x) = \mathbb{E}[g(x + X_T)]$,

$$
\mathcal{E}^+ g(x) = \mathbb{E}[g(x + X_T)], \quad \mathcal{E}^- g(x) = \mathbb{E}[g(x + X_T)],
$$

and, by definition,

$$
V(x; h) := \mathbb{E} \left[ \int_0^{T_h} e^{-qt} g(x + X_t) dt \right]
$$

$$
= \mathbb{E} \left[ \int_0^\infty 1_{x + X_t > h} e^{-qt} g(x + X_t) dt \right]
$$

$$
= q^{-1} \mathbb{E}[g(x + X_T) 1_{x + X_T > h}].
$$

Applying Lemma 2, we continue

$$
V(x; h) = q^{-1} \mathbb{E}[g(x + X_T + X_T - X_T) 1_{x + X_T > h}]
$$

$$
= q^{-1} \mathbb{E}[1_{x + X_T > h} \mathcal{E}^+ g(x + X_T)]
$$

$$
= q^{-1} \mathcal{E}^- \mathbb{1}_{(h, +\infty)} \mathcal{E}^+ g(x).
$$
Option to abandon a non-decreasing stream

Find an optimal stopping time $\tau$, which maximizes

$$V(x) = \sup_{\tau} E_x^x \left[ \int_0^\tau e^{-qt} g(X_t) dt \right]$$

In many cases, for non-decreasing $g$, the optimal stopping time is $\tau_h^-$, the hitting time of a semi-infinite interval $(-\infty, h]$.

From

$$V(x; h) = q^{-1} \mathcal{E}^- \mathbf{1}_{(h, +\infty)} \mathcal{E}^+ g(x),$$

a natural candidate for the optimal exercise boundary is $h_*$ s.t.

$$\mathcal{E}^+ g(h_*) = 0.$$

(2)
Theorem 3

Assume that

a. \(X\) satisfies (ACP)-condition,

b. trajectories of the supremum (resp., infimum) process reach any subinterval of \((0, +\infty)\) (resp., \((-\infty, 0)\)) with non-zero probability, and

c. \(g\) is a continuous non-decreasing function that changes sign.

Then

(i) equation \(\mathcal{E}^+ g(h_*) = 0\) has a unique solution;

(ii) \(\tau_{h_*}^-\) is an optimal stopping time, and \(h_*\) is the unique optimal threshold;

(iii) the rational value of the stream (with the option to abandon it) is

\[
V_*(x) = q^{-1} \mathcal{E}^- \mathbb{1}_{(h_*, +\infty)} \mathcal{E}^+ g(x);
\]

(iv) there exists a non-increasing function \(W_*\) which is non-negative below \(h_*\) and 0 above \(h_*\) such that \(V_* = q^{-1} \mathcal{E}(W_* + g)\).
Bad News Principle for irreversible investment

Assume $g$ is non-decreasing and changes sign. Find optimal $\tau$

$$V(x) = \sup_{\tau} \mathbb{E}^x \left[ \int_{\tau}^{\infty} e^{-qt} g(X_t) dt \right]$$

Rewrite as

$$\mathbb{E}^x \left[ \int_{0}^{\infty} e^{-qt} g(X_t) dt \right] + \sup_{\tau} \mathbb{E}^x \left[ \int_{0}^{\tau} e^{-qt} (-g(X_t)) dt \right]$$

Second term: mirror reflection of the exit problem with $-g$ in place of $g$.

The final answer:

$$V^*(x) = q^{-1} \mathcal{E} g(x) - q^{-1} \mathcal{E}^+ \mathbb{1}_{(-\infty, h^*)} \mathcal{E}^- g(x)$$

$$= q^{-1} \mathcal{E}^+ \mathbb{1}_{[h^*, +\infty)} \mathcal{E}^- g(x),$$

where $h^*$ is a unique solution to

$$\mathcal{E}^- g(h) = \mathbb{E} \left[ \int_{0}^{\infty} g(h + X_t) dt \right] = 0.$$
Regime-switching models

### General set-up and notation

- **finite state Markov chain**
- $\lambda_{jk}$ – transition rates; $\Lambda_j = \sum_{k \neq j} \lambda_{jk}$
- $X_t^{(j)}$ – Lévy process in state $j$
- $\psi_j$ and $L_j$: characteristic exponent and infinitesimal generator of $X_t^{(j)}$
- Jumps and switches do not happen simultaneously, a.s.
- $q_j$ – state-$j$ riskless rate
- $g_j$ – payoff stream in state $j$
- $G_j$ – instantaneous payoff in state $j$
Regime-switching models

Regularity conditions: for each \( j \)

(i) \( X_t^{(j)} \) satisfies (ACP)-property, and trajectories of the supremum (resp., infimum) process reach any subinterval of \((0, +\infty)\) (resp., \((-\infty, 0)\)) with non-zero probability

(ii) \( g_j \) is continuous, monotone, and does not grow too fast at infinity

(iii) \((q_j + \Lambda_j - L_j)G_j\) is continuous, monotone, and does not grow too fast at infinity
I. reduce an optimal stopping problem to option to abandon a stream

II. assuming that the value functions in each state but state $j$ are known and monotone, apply Theorem 3 and find the state-$j$ optimal exercise boundary and option value

III. using this conditional result as a guide, construct an iteration scheme, for all states, and prove that the boundaries and value functions converge to some limits

IV. using general sufficient conditions of optimality, prove that the limits give a solution to the optimal stopping problem

V. using Theorem 3 in each state once again, conclude that this solution is unique in the class of stopping times of threshold type.
Step II

Assuming that the reduction to the exit problem has been made, consider the option to abandon a stream

\[ g(X_t) = (g(j_t, X_t^{(j)})) = \left( g_j(X_t^{(j)}) \right)_{j=1}^m, \]

with a slight abuse of notation.

Fix \( j \) and assume that value functions \( V_k, k \neq j \), are sufficiently regular. Then

\[ V_j(x) = E_x \left[ \int_0^{\tau_j^-} e^{-(q_j + \Lambda_j)t} \left( g_j(X_t^{(j)}) + \sum_{k \neq j} \lambda_{jk} V_k(X_t^{(j)}) \right) dt \right], \quad (4) \]

where \( \tau_j^- \) is an optimal time to exit in state \( j \).
Using $q_j + \Lambda_j$ and $X^{(j)}$ in place of $q$ and a Lévy process $X$, we construct the normalized EPV-operators $\mathcal{E}_j, \mathcal{E}_j^-, \mathcal{E}_j^+.$

**Theorem 4**

a) Function $w_{j,*} = \mathcal{E}_j^+(g_j + \sum_{k \neq j} \lambda_{jk} V_{k,*})$ is continuous; it increases and changes sign;

b) equation $w_{j,*}(h) = 0$ has a unique solution, denote it $h_{j,*};$

c) the hitting time of $(-\infty, h_{j,*}]$ is an optimal stopping time, and $h_{j,*}$ is the optimal threshold;

d) state-$j$ value of the stream with the option to abandon the stream is given by

$$V_{j,*} = (q_j + \Lambda_j)^{-1} \mathcal{E}_j^{-} 1(h_{j,*}, +\infty) w_{j,*};$$

(5)

e) function $V_{j,*}$ vanishes below $h_{j,*}$ and increases on $[h_{j,*}, +\infty).$

The resulting system can be solved using the iteration procedure with 0 as the initial approximations for the value functions
### Assumptions: for $j = 1, \ldots, m$,

1. $G_j$ decrease and change sign;
2. $L_j G_j$ is well-defined;
3. $\tilde{g}_j = \sum_{k \neq j} \lambda_{jk} G_k - (q_j + \Lambda_j - L_j)G_j$ does not decrease, and $\tilde{g}_j(-\infty) < 0$

### Example: for $G_j(x) = K_j - B_j e^x$

1. $B_j, K_j > 0$;
2. $\psi_j$ admits the analytic continuation into the strip $\text{Im} \xi \in [-1, 0]$;
3. $q_j + \sum_{k \neq j} \lambda_{jk} (1 - K_k/K_j) > 0 \geq -\psi_j(-i) - q_j + \sum_{k \neq j} \lambda_{jk} (B_k/B_j - 1)$

RHS: minus dividend rate. LHS: effective discount rate for the strike price.
Algorithm

1. Choose \( (0 =) t_0 < t_1 < \cdots < t_N (= T) \).
2. For \( s = N - 1, N - 2, \ldots, \)
   - set \( \Delta_s = t_{s+1} - t_s, q_s^j = q_j + \Lambda_j + \Delta_s^{-1} \)
   - construct the EPV–operators \( \mathcal{E}_j^{s,-}, \mathcal{E}_j^{s,+} \) using \( X(j) \) and \( q = q_s^j \)
3. Set \( v_{j,*}^N = (G_j)_+, j = 1, 2, \ldots, m \).
4. For \( s = N - 1, N - 2, \ldots, \) denote by \( v_{j,*}^s, h_{j,*}^s \) the Carr’s randomization approximations to state-\( j \) option value and exercise boundary for interval \([t_s, t_{s+1})\):
   - assume that \( v_{j,*}^{s+1}, j = 1, 2, \ldots, m, \) are known
   - calculate the (approximations to the) exercise boundaries \( h_{j,*}^s \) and option values \( v_{j,*}^s, j = 1, 2, \ldots, m \)
Backward induction:

For each $s = N - 1, N - 2, \ldots$ and $j = 1, 2, \ldots, m$, we construct sequences \( \{ h_{jn}^s \}_{n=0}^{\infty} \) and \( \{ v_{jn}^s \}_{n=0}^{\infty} \), s.t.

\[
\begin{align*}
    h_{j,*}^s &= \lim_{n \to +\infty} h_{jn}^s, \\
    v_{j,*}^s &= \lim_{n \to +\infty} v_{jn}^s
\end{align*}
\]  

(6)

Thus, for each $s$, we need to introduce an additional cycle in $n$; and inside the cycle in $n$, we use additional cycles in $j = 1, 2, \ldots, m$. 

Boyarchenko and Levendorskiĭ (UT)  
Wiener-Hopf factorization  
November 20, 2008  33 / 40
At step \( s = N - 1, N - 2, \ldots \)

- for \( j = 1, \ldots, m \), set \( v_j^{s0} = 0, h_j^{s0} = +\infty \),
- for \( j = 1, \ldots, m \), calculate
  \[
  w_{0j}^s = -\mathcal{E}_j^{s,+}(q_j^s - L_j)G_j = q_j^s(\mathcal{E}_j^{s,-})^{-1}G_j,
  \]
- for \( n = 1, 2, \ldots \), for each \( j \), calculate
  \[
  \begin{align*}
  (i) & \quad w_j^{sn} = \mathcal{E}_j^{s,+} \left( \sum_{k \neq j} \lambda_{jk} v_k^{s,n-1} + \Delta_s^{-1} v_j^{s+1} \right) \\
  (ii) & \quad \tilde{w}_j^{sn} = w_j^{sn} + w_{0j}^s; \\
  (iii) & \quad h_j^{sn}, \text{ the solution of the equation } \tilde{w}_j^{sn}(h) = 0; \\
  (iv) & \quad v_j^{sn} = (q_j^s)^{-1} \mathcal{E}_j^{s,-} \left( \mathbb{1}_{(-\infty, h_j^{sn}]}(-w_{j0}^s) + \mathbb{1}_{(h_j^{sn}, +\infty)} w_j^{sn} \right)
  \end{align*}
  \]
- stop cycle in \( n \) when \( \max_j \sup_x |v_j^{s,n+1}(x) - v_j^{sn}(x)| < \epsilon \).
Non-dividend paying stock

The stock dynamics, $S_t$, stock volatility, $\hat{\nu}_t$, and the riskless interest rate, $r_t$, follow the system of SDE

\[
\frac{dS_t}{S_t} = r_t dt + \sqrt{\hat{\nu}_t} d\hat{W}_{1,t},
\]
\[
d\hat{\nu}_t = \hat{\kappa}_v (\hat{\theta}_v - \hat{\nu}_t) dt + \hat{\sigma}_v \sqrt{\hat{\nu}_t} dW_{2,t},
\]
\[
dr_t = \kappa_r (\theta_r - r_t) dt + \sigma_r \sqrt{r_t} dW_{3,t},
\]

where $\hat{W}_{1,t}$, $W_{2,t}$, $W_{3,t}$ are components of the Brownian motion in 3D, with unit variances. For simplicity, only $\hat{W}_{1,t}$ and $W_{2,t}$ are correlated, the correlation coefficient being $\rho$. The coefficients $\hat{\kappa}_v$, $\kappa_r$, $\hat{\theta}_v$, $\theta_r$, $\hat{\sigma}_v$ and $\sigma_r$ are positive.

- M&S: “Up to now, there exist no feasible methodology for pricing American options when volatility and interest rates are stochastic.”
- M&S develop an asymptotic method based on a certain suboptimal exercise rule, which they regard as intuitively natural.
- The method leads to an asymptotic expansion with terms given by analytic expressions, therefore, formally, Greeks can be calculated quite easily.
- M&S produce a numerical example of Heston model with CIR interest rates, and compare the results with the results obtained by Longstaff-Schwarz algorithm with 200,000 sample paths, 500 time steps and 50 exercise dates.
American put in Heston model with CIR interest rates

We consider the same example. The parameters are \( \hat{\kappa}_v = 1.58, \hat{\theta}_v = 0.03, \hat{\sigma}_v = 0.2, \kappa_r = 0.26, \theta_r = 0.04, \sigma_r = 0.08, \rho = -0.26 \), the spot value of the riskless rate is 0.04, the spot stock price is \( S = 100 \), the spot volatility \( v \) and strike \( K \) vary: \( v = 0.04, 0.09, 0.16, K = 90, 100, 110 \), and time to expiry is \( T = 1/12, 0.25, 0.5 \).

In the tables below

- (AP): prices of the American put calculated using discretization of \( (t, v, r) \)–space and the reduction to a regime-switching model;
- (MC): prices of the American put calculated in Medvedev and Scaillet (2007) using the Longstaff-Schwarz algorithm with 200,000 sample paths, 500 time steps and 50 exercise dates;
- (MS): prices of the American put, which Medvedev and Scaillet (2007) calculated using their asymptotic method with 5 terms of the asymptotic expansion.
